More than 23 million patients undergo operations each year in the United States. Prevention of perioperative complications remains one of the most important aspects of clinical care in patients undergoing surgical treatment. Venous thromboembolism (VTE) is a major threat to surgical patients during the perioperative period. VTE, which occurs with a relatively high frequency among surgical patients, refers to thrombotic occlusion within the venous system and includes deep vein thrombosis (DVT) and pulmonary embolism (PE). Because DVT typically occurs in the lower extremity, this condition is further defined as distal DVT (occlusion confined to the deep calf veins) or proximal DVT (thrombosis at or above the popliteal vein). Without appropriate prophylaxis against VTE, a distal or proximal DVT may result in PE, which can be fatal.

In the absence of prophylaxis, DVT occurs after approximately 20% of all major surgical procedures and PE occurs after 1% to 2%. The prevalence of VTE is even higher in orthopedic patients: more than 50% of major orthopedic procedures are complicated by DVT and up to 30% by PE when VTE prophylaxis is not instituted. Without prophylaxis, the frequency of fatal postoperative PE ranges from 0.1% to 0.4% in patients undergoing elective general surgery and from 1% to 5% in patients undergoing elective hip or knee surgery, emergency hip surgery, and surgery for major trauma or spinal cord injury.

The emphasis on prevention of VTE, as opposed to treating only symptomatic episodes, has a multifactorial rationale. Although most cases of postsurgical VTE remain asymptomatic, VTE is associated with significant morbidity, mortality, and costs of care. The 1-year mortality rate of DVT is estimated to be 16% to 30%, with most deaths occurring within the first month. VTE prophylaxis does not afford complete protection; however, it has been shown to be cost-effective as well as clinically efficacious, with DVT rates...
reduced by 70% or more. In addition, prophylactic anticoagulation therapy is effective in preventing DVT and PE-related mortality. However, studies continue to show common underutilization of VTE prophylaxis. Observational studies have documented that nearly half of hospitalized patients who developed DVT did not receive adequate VTE prophylaxis. Additionally, autopsy studies have demonstrated that for the majority of cases of confirmed PE, this diagnosis was not considered prior to death. Barriers to appropriate VTE prophylaxis include the perception that VTE is uncommon, a lack of acceptance of the importance of VTE prophylaxis, and concerns about hemorrhagic complications in surgical patients.

This article reviews the epidemiology of VTE, the methods for achieving VTE prophylaxis, and the approach to instituting VTE prophylaxis in surgical patients.

**RISK FACTORS, PATHOGENESIS, AND CLINICAL COURSE**

Patients undergoing surgical procedures are at an increased risk for developing VTE, due in part to the physiologic stress as well as potential postoperative immobility. VTE often results from a combination of risk factors, including inherited, acquired, environmental, and idiopathic conditions. Relevant risk factors leading to the development of VTE vary widely and include factors such as age, type of surgery, duration of postoperative immobilization, underlying medical comorbidities, hypercoagulable disorders, and malignancy (Table 1).

The pathogenesis of venous thrombosis involves Virchow’s triad: damage to the vessel wall, venous stasis, and hypercoagulability. VTE typically originates in the venous sinuses of the calf muscles but can occur in the proximal veins due to trauma or surgery. Twenty-five percent of postoperative DVT cases involve proximal deep veins, which are much more likely to cause symptoms and result in PE. Of distal DVT cases, 10% to 20% are thought to propagate to proximal DVT. It has been estimated that half or more of DVTs
begin intraoperatively.\textsuperscript{2,21} Several of these clots resolve spontaneously, and the addition of postoperative prophylactic agents facilitates this resolution. For patients at greatest risk, longer duration of prophylaxis correlates with further reductions in the incidence of DVT, which adds evidence to the concept that many cases of DVT occur later in the postoperative course.

Associated signs and symptoms of DVT result from venous outflow obstruction and from inflammation of the vessel wall and perivascular tissue.\textsuperscript{18} The potential complications of DVT include worsening acute venous symptoms with development of phlegmasia and possible limb loss; development of PE and subsequent death; recurrent thromboembolic events; and the development of chronic venous insufficiency due to postthrombotic syndrome. In phlegmasia cerulea dolens, the thrombosis extends to collateral veins, which can lead to massive fluid sequestration. Clinical symptoms include significant leg swelling, bluish discoloration, and pain. In phlegmasia alba dolens, the thrombosis involves major deep venous channels of the extremity, therefore sparing collateral veins. The venous drainage is decreased but still present, and it is frequently associated with lymphangitis. Clinical symptoms include a large, swollen, and painful limb made pale by severe edema. Limb loss can be a devastating sequela if phlegmasia is left untreated. Calf vein thrombi often undergo spontaneous thrombolysis but rarely result in symptomatic PE,\textsuperscript{22} however, approximately 25% of untreated calf thrombi extend into the proximal veins, usually within a week after presentation.\textsuperscript{23} The risk of PE (either symptomatic or asymptomatic) with proximal DVT is approximately 50%, and most fatal emboli usually originate from proximal thrombi.\textsuperscript{24,25} The development of postthrombotic syndrome is a function of the extent of thrombosis, its subsequent effect on venous valvular competence, and long-term residual obstruction. The consequences of postthrombotic syndrome and chronic venous insufficiency are quite severe, with persistent edema, pain, and recurring skin problems (eg, ulcerations). These problems lead to decreased quality of life and considerable economic burden.

**PHARMACOLOGIC PROPHYLAXIS**

Pharmacologic prophylaxis is the most effective modality for prevention of VTE in surgical patients. A brief review of the mechanisms of action is provided as a basis for understanding the different drugs and their unique properties. Commonly used antithrombotic dosing regimens for VTE prophylaxis are shown in Table 3.\textsuperscript{26}

GCS = graduated compression stockings; INR = international normalized ratio; IPC = intermittent pneumatic compression devices; LMWH = low-molecular-weight heparin; UFH = unfractionated heparin; VKA = vitamin K antagonist; VTE = venous thromboembolism.

Permission to electronically reproduce this table not granted by copyright holder.
At therapeutic concentrations, heparin has a half-life of about 60 minutes. Its clearance is dose dependent. Heparin has decreased bioavailability when administered subcutaneously in low doses but has approximately 90% bioavailability when administered in high therapeutic doses.25

Low-dose unfractionated heparin (UFH) has been in clinical use for many years. In general surgery patients, UFH has been shown to reduce VTE by 70%.29 A downside to UFH is the unpredictable treatment response to full anticoagulation. Heparin binds to a number of plasma proteins, a phenomenon that reduces its anticoagulant effect by limiting the accessibility of heparin to antithrombin. The concentration of heparin-binding proteins also increases during illness, which contributes to the variability in anticoagulant response.30 Because of this variability, response to heparin should be monitored with the activated partial thromboplastin time (aPTT). The dose should be adjusted as necessary to achieve a therapeutic range, which for many aPTT reagents corresponds to an aPTT ratio of 1.5 to 2.5.26 It is also this binding to plasma proteins, specifically platelet factor 4, that can lead to heparin-induced thrombocytopenia (HIT).31,32

Standard prophylactic dosing for patients undergoing general surgical procedures is typically 5000 U of low-dose UFH subcutaneously 1 to 2 hours preoperatively, which is continued 2 or 3 times daily postoperatively until the patient is ambulatory or is discharged home.19 For orthopedic patients, low-dose UFH is typically given at a dose of 5000 U subcutaneously 2 hours before surgery and 5000 U every 8 or 12 hours after surgery.7 The more frequent dosing schedule seems to be somewhat more effective without any increased complications noted. Risk for major bleeding from UFH in prophylactic doses has not been found to exceed that of placebo; however, risk for wound hematomas has been shown to be 2% higher with UFH than with placebo.30 Higher rates of osteopenia and osteoporosis have also been reported in patients treated with long-term UFH.33

**Low-molecular-weight heparin.** Low-molecular-weight heparin (LMWH) is derived from standard commercial-grade heparin by chemical depolymerization to yield fragments approximately one third the size of heparin.27 Depolymerization changes the anticoagulant profile, bioavailability, and pharmacokinetics of heparin, resulting in a lower incidence of HIT and of osteopenia.26,28 LMWH works by binding to and markedly enhancing the activity of antithrombin. In contrast to UFH, there is much more specificity against factor Xa with very little effect against thrombin. Decreased binding to plasma proteins translates into increased bioavailability and longer half-life, enabling weight-based daily dosing without laboratory monitoring. Another benefit of LMWH is that long-term dosing is associated with lower rates of osteoporosis than with UFH.34

In contrast to UFH, LMWH is cleared almost entirely by the kidneys. Renal clearance of LMWH is therefore less predictable in patients with severe renal insufficiency, defined in most studies as a creatinine clearance of less than 30 mL/min. In these patients, laboratory monitoring of anti-Xa levels is prudent. LMWH dosing is also less predictable in morbidly obese patients (body mass index > 50) due to metabolic variables and may require monitoring during full anticoagulation. Decreased binding to plasma proteins, specifically platelet factor 4, results in a decreased incidence of HIT. Even so, patients with HIT should not receive LMWH, because cross-reactivity with UFH does occur.31,32

The LMWHs used in VTE prophylaxis are enoxaparin, dalteparin, danaparoid, and nadroparin. Dosing

</table>

INR = international normalized ratio; IV = intravenous; PO = by mouth; PT = prothrombin time; SC = subcutaneously; UFH = unfractionated heparin; VTE = venous thromboembolism.

*Approved for use in hip fracture surgery, knee replacement surgery, and hip replacement surgery. Fondaparinux is the only US Food and Drug Administration–approved anticoagulant drug for hip fracture surgery. It is also approved for extended prophylactic dosing (21 days) following hip fracture surgery.
regimens for enoxaparin and dalteparin are provided in Table 3.

**Fondaparinux** is a new parenteral synthetic anticoagulant composed of the 5 saccharide units that comprise the active site of heparin that binds antithrombin.\(^\text{25,36}\) The fondaparinux antithrombin complex inhibits factor Xa but has no direct activity against thrombin. Fondaparinux is rapidly absorbed and is 100% bioavailable when administered subcutaneously. Fondaparinux has better bioavailability and a longer half-life than LMWH. It is not metabolized, is renally excreted, and has a dose-independent elimination half-life of 15 hours, which makes it suitable for once-daily administration. Fondaparinux has been approved for thrombosis prophylaxis in hip and knee joint replacement surgery and is being evaluated for VTE prophylaxis in the high-risk abdominal patient. One potential advantage of fondaparinux over both LMWH and UFH is that the risk for HIT is substantially lower.\(^\text{37}\) The dosing regimen for fondaparinux is provided in Table 3.

**Warfarin.** Warfarin is an oral anticoagulant that competitively inhibits production of vitamin K–dependent clotting factors in the liver by producing hemostatically defective, vitamin K–dependent coagulant proteins (prothrombin; factors VII, IX, and X; and the anticoagulant proteins C and S).\(^\text{38}\) Warfarin is completely absorbed after oral administration, with peak concentration generally achieved within the first 4 hours. Its anticoagulation effect generally occurs within 24 hours after drug administration. However, peak anticoagulant effect may be delayed 72 to 96 hours. The duration of action of a single dose of this anticoagulant ranges from 2 to 5 days. The elimination of warfarin is completely by metabolism, with its metabolites principally excreted into the urine.\(^\text{34}\)

The dose of warfarin must be monitored closely because the anticoagulant response varies widely among individuals. Laboratory monitoring is performed by measuring the prothrombin time (PT), a test responsive to depression of 3 of the 4 vitamin K–dependent clotting factors (prothrombin and factors VII and X). Commercial PT reagents vary markedly in their responsiveness to warfarin-induced reduction in clotting factors, a problem that has been overcome by the introduction of the international normalized ratio (INR).\(^\text{39}\)

The starting dose of warfarin is typically 10 mg, with an average maintenance dose of approximately 5 mg. Elderly patients require lower doses. Evidence indicates that it might be safer to use a starting dose of 5 mg of warfarin because, compared with 10 mg, the 5-mg starting dose does not result in a delay in achieving a therapeutic INR and is associated with a lower incidence of supratherapeutic INR values during the first 5 days of treatment.\(^\text{39}\) In some patients, unexpected fluctuations in dose response occur, which may reflect changes in diet, inaccuracy in PT testing, undisclosed drug use, poor compliance, or surreptitious self-medication. Patients receiving warfarin are also sensitive to fluctuating levels of dietary vitamin K, which is obtained predominantly from leafy green vegetables. The effect of warfarin can be potentiated in sick patients with poor vitamin K intake, if they are treated with antibiotics and intravenous feeding without vitamin K supplementation, and in states of fat malabsorption.

Moderate-dose warfarin (INR, 2.0–3.0) is effective for preventing postoperative VTE in patients in all risk categories.\(^\text{39}\) Warfarin therapy can be started preoperatively, at the time of surgery, or in the early postoperative period. Although the anticoagulant effect is not achieved until the third or fourth postoperative day, warfarin treatment started at the time of surgery or in the early postoperative period is effective in highest-risk patients, including patients with hip fractures and those who undergo joint replacement. However, warfarin is not generally used for perioperative VTE prophylaxis in surgical patients as it typically requires several days to reach its therapeutic level. In addition, prophylaxis with warfarin is less convenient than prophylaxis with low-dose UFH or LMWHs because warfarin requires careful laboratory monitoring.

**Antiplatelet Therapy**

Aspirin is a nonsteroidal anti-inflammatory drug commonly used in treating fever, pain, and bodily inflammation. Aspirin exerts its pharmacologic effect by suppressing the production of prostaglandins and thromboxanes via irreversible inhibition of the cyclooxygenase enzymes. Prostaglandins are hormones that have diverse effects in the body, including but not limited to transmission of pain information to the brain, modulation of the hypothalamic thermostat, and inflammation. Thromboxanes are responsible for the aggregation of platelets that leads to formation of an intraluminal thrombus.\(^\text{40}\) Because aspirin can inhibit platelet aggregation, it has been considered for VTE prophylaxis. However, aspirin therapy is considered ineffective for VTE prophylaxis in surgical patients. Original support for its usage came from collections of very small studies with small numbers of patients, which are quite old. More modern studies involving aspirin have shown that it is far inferior to LMWHs and UFH.\(^\text{19,41,42}\) Additionally, aspirin has been linked to increased risk of bleeding, which further discourages its use.\(^\text{40}\) Given the available
literature, antiplatelet therapy is not the standard of care
for the prevention of VTE in surgical patients.

Direct Thrombin Inhibitors

Ximelagatran is a direct thrombin inhibitor that is
currently being evaluated for primary prevention and
acute and long-term treatment of VTE. Ximelagatran
has no known food or drug interactions and is admin-
istered orally. Once absorbed from the gastrointestinal
tract, ximelagatran is converted to melagatran, a partial
mimetic of fibrinopeptide A, which blocks the active site
of thrombin. Ximelagatran is primarily eliminated by
the kidneys and has a half-life of about 3 hours, mandat-
ing twice-daily administration. It has been studied for
VTE prophylaxis in orthopedic patients and appears to be
equally efficacious as LMWH. However, it has not yet
received US Food and Drug Administration approval.

Complications of Antithrombotic Therapy

Bleeding remains the most common complication of
antithrombotic therapy. The risk of bleeding caused
by antithrombotic agents is influenced by the dose and
by patient-related factors, the most important being
recent surgery or trauma. Other patient characteristics
that increase the risk of bleeding are older age, recent
stroke, generalized hemostatic defect, a history of gas-
trointestinal hemorrhage, and serious comorbid condi-
tions. Bleeding complications with UFH and LMWHs
are similar. With UFH, the incidence of bleeding is
influenced by dosage and by means of administration,
bleeding events being more common with intermittent
intravenous therapy than with continuous intravenous
therapy. The incidence of bleeding complications with
fondaparinux is higher than with LMWHs. Bleeding
associated with warfarin is influenced by the intensity of
anticoagulant therapy. The risk for bleeding is reduced
by approximately one third if the targeted INR range
is lowered from between 3.0 and 4.5 to between 2.0
and 3.0. Both heparin-induced bleeding and warfarin-
induced bleeding are increased by concomitant use of
aspirin, which impairs platelet function and produces
gastric erosions. When the INR is less than 3.0, warfarin-
associated bleeding frequently has an obvious underlying
cause or is from an occult gastrointestinal or renal lesion.

Nonhemorrhagic side effects of heparin include the
following: (1) urticaria at sites of subcutaneous injec-
tion; (2) thrombocytopenia, which occurs in 2% to
4% of patients treated with high-dose heparin and is
complicated by arterial or venous thrombosis in about
0.2% of treated patients; (3) osteoporosis and osteope-
nia, which occur with prolonged high-dose heparin use;
and (4) alopecia, adrenal insufficiency, and skin necro-
sis (all of which are rare). The incidence of throm-
boctopenia is lower with LMWHs than with heparin.
Similarly, there is evidence that the risk of osteopenia is
lower with LMWH than with heparin.

The most important nonhemorrhagic side effect of
warfarin is skin necrosis, an uncommon complication
usually observed on the third to eighth day of therapy.
Skin necrosis is caused by extensive thrombosis of the
venules and capillaries within the subcutaneous fat.
An association has been reported between warfarin-
induced skin necrosis and protein C deficiency and, less
commonly, protein S deficiency (this complication can
also occur in patients without these deficiencies).
Because warfarin inhibits vitamin–K dependent coagula-
tion factors, including protein C and S, patients who re-
quire antithrombotic therapy should receive heparin or
LMWH first and then be transitioned to warfarin oral
anticoagulation. This approach reduces the likelihood of
depleting protein C or S levels in these patients.

NONPHARMACOLOGIC PROPHYLAXIS

Mechanical Prophylaxis

Mechanical prophylaxis is an attractive option for VTE
prophylaxis because there is no associated increased risk
of bleeding. It is therefore most useful in patients who
are deemed to be at high risk for bleeding complications
from pharmacologic prophylaxis. Mechanical means of
VTE prophylaxis include graduated compression stock-
ings (GCS), intermittent pneumatic compression (IPC)
devices, and venous foot pumps (Table 2). The latter 2
devices rely on a common mechanical principle of pro-
viding an intermittent compressive effect on the lower
venous circulation. Their mechanism of action is reduc-
tion in stasis and perhaps a local increase in fibrinolytic
activity. Both GCS and IPC devices increase venous blood
flow and decrease venous stasis. IPC devices also stimu-
late endogenous fibrinolytic activity by causing gentle
trauma to the vascular endothelial cells of the lower leg
and by altering rheological characteristics and perfusion
pressure. Because the history of venous foot pumps
in VTE prophylaxis is relatively recent, the role of these
devices as a sole means of VTE prophylaxis in surgical
patients remains to be validated. IPC is the method of
choice for preventing VTE in patients undergoing neu-
rosurgery, is effective in patients undergoing major knee
surgery, and is as effective as low-dose UFH in patients
undergoing abdominal surgery. GCS are relatively inex-
pensive and should be considered in all high-risk surgical
patients, even if other forms of prophylaxis are used.
GCS should be used with caution in patients with signi-
cificant arterial insufficiency as there have been reports of
worsening limb ischemia and tissue loss.
In direct comparison studies, mechanical prophylaxis has been found to be better than no prophylaxis but less effective than pharmacologic means.\textsuperscript{56} When mechanical prophylaxis is combined with pharmacologic prophylaxis, there is enhanced protection over pharmacologic treatment alone. This additive effect is predictable, based on the approach of both relieving venous stasis and correcting or preventing hypercoagulability.\textsuperscript{21,56–59}

Perhaps the biggest problem with mechanical prophylaxis, however, is compliance. Stockings must be adequately sized and properly fitted. Compression devices only work while in place and commonly are found at the foot of the bed or on the floor in the patient’s room in clinical practice. Patient compliance with mechanical prophylaxis is generally well maintained when the treatment is conducted within a clinical study protocol. However, it appears that outside clinical trials where compliance is carefully maintained, day-to-day use proves less reliable and is less efficacious.

**Inferior Vena Cava Filters**

Placements of prophylactic inferior vena cava (IVC) filters is effective for prevention of PE. Naturally, there is no impact on incidence of DVT, as it is not a prophylactic measure against DVT. Accepted indications for IVC filters are patients with PE despite anticoagulation, patients with symptomatic VTE and a contraindication to anticoagulation or a complication of anticoagulation, and patients requiring pulmonary embolectomy for PE.\textsuperscript{60} Relative indications have included patients with a large DVT (“free floating” iliofemoral DVT), problems with compliance with anticoagulation therapy, and patients with VTE and limited cardiopulmonary reserve.

Although the incidence of complications is small, IVC filters pose some risk of caval thrombosis and, by some reports, increase the chance of a future DVT. Therefore, IVC filters can be safely removed after a long period. These factors led to the recent development of retrievable IVC filters. IVC filters can be safely removed as long as 1 year after implantation, which has encouraged the placement of these filters in a large number of patients. Prophylactic retrievable IVC filters have been most commonly placed in patients felt to be at high risk for VTE, in whom anticoagulation is not advisable or is contraindicated (eg, trauma patients with spine or brain injuries, patients undergoing bariatric surgery). Review of the literature, however, shows no strong evidence to support those practices, as PE is still an uncommon occurrence even in highest-risk groups.\textsuperscript{60}

The indications for placement of retrievable IVC filters, therefore, remain in evolution and currently must be based on individual or regional practice patterns until large trials are available to provide evidence to support specific recommendations. The ACCP guidelines do not currently recommend the use of IVC filters.\textsuperscript{19}

**APPROACH TO PRIMARY PROPHYLAXIS OF VTE**

The most effective approach to reducing VTE-related morbidity and mortality is to institute primary prophylaxis in patients at risk for VTE. Based on well-defined clinical criteria, the 2004 ACCP recommendations\textsuperscript{19} for VTE prophylaxis classify surgical patients as low, moderate, high, or highest risk for VTE (Table 2).\textsuperscript{14}

The choice of prophylaxis should be tailored to the patient’s risk. Clearly, early mobilization is the least costly, and, for many low-risk patients, a highly effective method of VTE prophylaxis. For patients who are medically and physically able to get out of bed and are at low risk for VTE, this is sufficient. Immobilized or higher-risk patients require a more active means of VTE prophylaxis, which is accomplished either by modulating activation of blood coagulation or by preventing venous stasis by using the following proven approaches: low-dose subcutaneous UFH, IPC of the legs, warfarin, adjusted doses of subcutaneous UFH, GCS, LMWH, or fondaparinux.\textsuperscript{6,61,62}

**Indications for Prophylaxis**

**General surgery.** Clearly, the type and length of surgery are directly related to the incidence of VTE. As always, the approach to prophylaxis should be tailored to the patient’s risk for developing VTE (Table 2). In the low-risk group of patients (patients undergoing relatively minor procedures [eg, laparoscopic cholecystectomy]), no specific prophylaxis other than early mobilization is needed based on the extremely low incidence of VTE in this patient population. Higher-risk patients require active prophylaxis. In general, UFH and LMWH are more efficacious than mechanical prophylaxis alone, and patients treated with LMWH are less likely to develop symptomatic DVT. However, the overall incidence of symptomatic DVT, PE, complications, and death are similar between the 2 agents.\textsuperscript{19} Prophylaxis recommendations for moderate-risk patients are UFH twice daily or LMWH and for high-risk patients are UFH 3 times daily or LMWH. Highest-risk patients should receive UFH 3 times daily or LMWH combined with GCS and/or IPC. In select general surgery patients at highest risk (eg, those undergoing cancer surgery), consideration should be given to prolonged prophylaxis (up to 1 mo) after hospital discharge. If anticoagulants are contraindicated because of an unusually high risk of bleeding, GCS, IPC of the legs, or both should be used.\textsuperscript{19}

**Trauma surgery.** Trauma patients, especially those...
with spinal cord injury, severe brain injury, pelvic fracture, or burns and those with lengthy periods of immobilization, are at very high risk for VTE, with a reported rate of 60% or greater. Pharmacologic VTE prophylaxis in this group has been studied, and LMWH has been found to be superior to UFH, with 60% less proximal DVT. Therefore, it is recommended that these patients receive LMWH. If the patients cannot be treated with LMWH because of bleeding concerns, mechanical prophylaxis should be initiated and then LMWH started once the risk of bleeding is reduced. For patients with prolonged immobility, including any period of inpatient rehabilitation, the ACCP recommends prophylaxis until discharge. Burn patients as well are at risk for VTE, and it is recommended that those with 1 additional risk factor for VTE begin prophylaxis with UFH or LMWH as soon as possible.

**Orthopedic surgery.** In general, LMWH, fondaparinux, and warfarin provide effective VTE prophylaxis in patients undergoing hip surgery, while LMWH, warfarin, fondaparinux, and IPC provide effective VTE prophylaxis in patients undergoing major knee surgery. The ACCP guidelines recommend that prophylaxis for all patients undergoing orthopedic operations should be at least 10 days. Extended prophylaxis with LMWH or warfarin for 28 to 35 days after hospital discharge should be considered after major orthopedic surgery. Extended prophylaxis is also strongly recommended for high-risk patients (eg, patients with previous VTE or active cancer).

Low-dose UFH is less effective than warfarin, adjusted-dose heparin, or LMWHs in patients undergoing major orthopedic surgical procedures. For patients undergoing hip or major knee surgery, LMWH is more effective than warfarin but is also associated with more frequent bleeding, both of which may be caused by a more rapid onset of anticoagulation with postoperatively initiated LMWH than with warfarin. It is uncertain whether the superior efficacy of LMWH over warfarin in preventing venographically detectable venous thrombosis is mirrored by fewer symptomatic episodes of VTE with LMWH. Results in joint surgery patients suggest that fondaparinux is somewhat more effective than LMWH but is also associated with a higher incidence of bleeding complications. The relative efficacy and safety of aspirin versus LMWH, fondaparinux, or warfarin in patients who have a hip fracture or have undergone hip or knee arthroplasty is uncertain. However, studies have shown that aspirin is much less effective than LMWH or warfarin at preventing venographically detectable venous thrombosis. Therefore, aspirin is not recommended as the sole agent for postoperative prophylaxis. Ultimately, selection of a prophylactic agent must be based on the patient’s specific risk profile for complications.

ACCP recommendations for VTE prophylaxis for specific orthopedic procedures are summarized below.

- **Elective hip or knee arthroplasty.** Patients undergoing elective total hip replacement should receive 1 of the following VTE prophylaxis strategies: (1) LMWH (at a usual high-risk dose, started 12 hr before surgery or 12–24 hr after surgery; or 4–6 hr after surgery at half the usual high-risk dose and then increasing to the usual high-risk dose the following day); (2) fondaparinux (2.5 mg started 6–8 hr after surgery); or (3) adjusted-dose warfarin started preoperatively or the evening after surgery (INR target, 2.5; INR range, 2.0–3.0). Patients undergoing elective knee arthroplasty should receive VTE prophylaxis with LMWH (using a high-risk dose), fondaparinux (2.5 mg/day), or adjusted-dose warfarin (target INR, 2.5; INR range, 2.0–3.0).

- **Knee arthroplasty.** Low-risk patients do not require any specific prophylaxis intervention other than early mobilization. In patients at higher risk due to preexisting VTE risk factors or following a prolonged/complicated procedure, LMWH is indicated.

- **Hip fracture surgery.** Patients undergoing hip fracture surgery should receive routine fondaparinux, LMWH at the usual high-risk dose, low-dose UFH, or adjusted-dose warfarin (target INR, 2.5; INR range, 2.0–3.0). Patients whose surgery may be delayed should receive prophylaxis with low-dose UFH or LMWH during the time between hospital admission and surgery. In the event that anticoagulant prophylaxis is contraindicated due to high risk of bleeding during hip surgery, these patients should receive mechanical prophylaxis including both GCS and IPC.

**Vascular surgery.** Interestingly, vascular surgery patients appear to be at low risk for VTE. Randomized trials have demonstrated no benefit of prophylaxis over placebo, although the studies were small. The ACCP guidelines do not recommend any specific VTE prophylaxis unless additional risk factors are present, in which case, UFH or LMWH is recommended. Preoperative dosing is rarely needed as most of these patients receive UFH intraoperatively, but postoperative treatment should be considered for those who remain at bed rest for a prolonged period.

**Gynecologic and urologic surgery.** Based on the ACCP recommendations, no specific VTE prophylaxis is needed other than early mobilization for patients...
undergoing brief (<30 min) gynecologic surgery or transurethral or low-risk urologic procedures. Patients undergoing laparoscopic gynecologic surgical procedures who have additional VTE risk factors should undergo at least 1 of the VTE prophylactic strategies, such as low-dose UFH, LMWH, IPC, or GCS. All patients undergoing major gynecologic operations should receive VTE prophylaxis until they are discharged from the hospital. Elderly women (≥60 yr) undergoing gynecologic cancer surgery or who have had a previous episode of VTE should receive VTE prophylaxis for 2 to 4 weeks following hospital discharge.

Patients undergoing major or open urologic procedures should receive VTE prophylaxis, such as low-dose UFH 2 or 3 times daily. Alternative strategies may include LMWH, IPC, and/or GCS. Urologic patients with multiple VTE risk factors (Table 1) should be treated with combinations of GCS and/or IPC with low-dose UFH or LMWH.

Neurosurgery. Neurosurgery patients should routinely receive VTE prophylaxis. GCS reduce venous stasis and prevent postoperative VTE in surgical patients with neurologic disorders, including paralysis of the lower limbs. \(^1\) IPC with or without GCS is effective prophylaxis for VTE in patients undergoing intracranial surgery and does not increase the risk of bleeding. \(^6\) Alternatively, these patients can be treated with low-dose UFH or postoperative LMWH. High-risk neurosurgical patients with multiple VTE risk factors should receive a combination of mechanical prophylaxis (GCS and/or IPC) as well as pharmacologic prophylaxis, including low-dose UFH or LMWH.

CONCLUSION

Probably the most important factor in preventing VTE in surgical patients is recognizing the need to institute primary VTE prophylaxis. Choice of prophylactic modality is best based on risk group assessment. Pharmacologic prophylaxis continues to be the most effective method. Future developments will likely include the approval of oral agents with greatly improved ease of administration. The role for removable IV filters will hopefully become better defined with further study.
